# Establishing a Martian Greenhouse Effect Through Directed Impacts 

TEAM 190: Problem A - Terraforming Mars

November 15, 2015

#### Abstract

In this report we investigate the effectiveness of asteroid bombardment on Mars in creating a stable atmosphere which allows for the existence of liquid water. The impacts release thermal energy which temporarily raises the average temperature of the Martian atmosphere, thereby allowing carbon dioxide frozen in the poles to be released. We found total mass of the impactors to be $1.225 \times 10^{13} \mathrm{~kg}$, based on a required energy for atmospheric heating and $\mathrm{CO}_{2}$ sublimation of $2.14 \times 10^{21} \mathrm{~J}$. The impulse required to move these asteroids such that they collide with Mars is on the order of $10^{16} \mathrm{~N} *$ s.

## 1 Introduction

Humanity has been fascinated with Mars since its discovery by ancient civilizations thousands of years ago. The evidence of the past existence of liquid water on Mars' surface has reinvigorated this fascination, and given it a new focus. Modern scientific understanding puts the colonization of Mars in view by giving humanity the ability to approach the problems created by the inhospitable conditions on Mars' surface. In this report we approach the problem of Mars' low surface temperature. A significant amount of carbon dioxide is frozen at the poles, and if released could thicken Mars' atmosphere enough to maintain a temperature which permits liquid water to form. We hypothesize that driving asteroids into the surface of Mars would increase the average temperature to a point which drives the dry ice in the poles to sublimation. The positive-feedback loop caused by this sublimation would lead to a thicker atmosphere and more stable climate conditions.

## 2 Required Equilibrium Conditions

### 2.1 Conditions for Liquid Water

We want Mars to be able to sustain liquid water on its surface. To do this, we require Mars to have a surface air temperature of at least 273 K and a surface air pressure of at least 612 Pa . This was determined with the location of the triple point on the phase diagram of water ${ }^{[5]}$. Mars already has a sufficient surface air pressure of about $636 \mathrm{~Pa}^{[12]}$; however, Mars' surface temperature is another story.

### 2.2 Blackbody Temperatures

To achieve sustainable liquid water on Mars, we need Mars to have an average surface air temperature slightly above 273 K . Using the Stefan-Boltzmann equation, the blackbody temperature of Mars at equilibrium, $\mathrm{T}_{\text {Mars }}$, can be determined. $\mathrm{T}_{\text {Sun }}=5778 \mathrm{~K}^{[13]}$ is the blackbody temperature of the Sun (or surface temperature). $\mathrm{a}=0.17^{[12]}$ is the albedo of Mars. $R_{\text {Sun }}=6.96 \times 10^{8} \mathrm{~m}^{[13]}$ is the radius of the Sun. $D=2.2792 \times 10^{11} \mathrm{~m}^{[12]}$ is the average distance between Mars and the Sun.

$$
\begin{equation*}
T_{\mathrm{Mars}}=T_{\mathrm{Sun}}(1-a)^{\frac{1}{4}} \sqrt{\frac{R_{\text {Sun }}}{2 D}} \tag{1}
\end{equation*}
$$

We determine that the blackbody temperature of Mars is about 215 K , which isn't enough to satisfy the conditions for liquid water. As a comparison, Earth's blackbody temperature is about 254 K , which is also below 273K. Earth's average surface air temperature is actually much higher than 254 K . This is due to the greenhouse effect of various gases in Earth's atmosphere, such as $\mathrm{CO}_{2}, \mathrm{H}_{2} \mathrm{O}, \mathrm{CH}_{4}, \mathrm{CFCs}$ and so on. Mars' atmosphere is comprised of mostly $\mathrm{CO}_{2}$, and for the purposes of this report, we will consider that it is all $\mathrm{CO}_{2}$. Assuming this, we can model the effects of different $\mathrm{CO}_{2}$ levels on heating up Earth's atmosphere and apply it to Mars.

### 2.3 Optical Depth of $\mathrm{CO}_{2}$

We can determine the temperature change due to the greenhouse effect using the optical depth, $\tau(\mathrm{n})$, of certain concentrations, $n$, of gases in the atmosphere. We used a version of Ramanathan's semi-gray model shown in the equation below ${ }^{[8]}$, where $\mathrm{T}_{\mathrm{S}}$ is the surface air temperature after the greenhouse effect, $\mathrm{T}_{\mathrm{B}}$ is the blackbody temperature of the planet, and $\beta^{\sim} 0.7^{[8]}$ is a constant representing the ratio of electromagnetic radiation that is opaque to the gas.

$$
\begin{equation*}
\tau(n)=\frac{2}{3} \frac{2 T_{S}^{4}-T_{B}^{4}}{T_{B}^{4}-(1-\beta) T_{S}^{4}} \tag{2}
\end{equation*}
$$

The optical depth of $\mathrm{CO}_{2}$ on Earth before the industrial era was determined to be our reference to be about 1.73 , when the concentration of $\mathrm{CO}_{2}$ in the atmosphere was about $280 \mathrm{ppm}^{[8]}$. The effects of other greenhouse gases have already been considered by the source. The number density of $\mathrm{CO}_{2}$ on Earth at this time can be determined by using the concentration as a ratio of the number density of air (about $2.7 \times 10^{25} \mathrm{~m}^{-3[10]}$ ). The number density of $\mathrm{CO}_{2}$ on Earth before the industrial era was about $7.56 \times 10^{21} \mathrm{~m}^{-3}$.

The ratio of optical depths of different concentrations of $\mathrm{CO}_{2}$ is equal to the ratio of those concentrations. This is shown in the equation below ${ }^{[8]}$, where $\mathrm{n}_{0}$ is the pre-industrial concentration of $\mathrm{CO}_{2}$.

$$
\begin{equation*}
\tau_{\mathrm{CO}_{2}}(n)=\frac{n}{n_{0}} \tau_{C O_{2}}\left(n_{0}\right) \tag{3}
\end{equation*}
$$

This can be rewritten in terms of a ratio of number densities. $\mathrm{N}_{0}$ was determined earlier to be about $7.56 \times 10^{21} \mathrm{~m}^{-3}$.

$$
\begin{equation*}
\tau_{C O_{2}}(N)=\frac{N}{N_{0}} \tau_{C O_{2}}\left(N_{0}\right) \tag{4}
\end{equation*}
$$

Using Equation 2, we can determine the optical depths required for liquid water (we'll consider temperatures slightly higher than 273 K ).

Figure 1: The relation between the optical depth of $\mathrm{CO}_{2}$ and the surface air temperature

We will need an optical depth of at least 12.72 to provide an equilibrium surface air temperature of 273 K on Mars. Using equation 4, we can see that this corresponds to a number density of about $5.56 \times 10^{22} \mathrm{~m}^{-3}$, or a mass density of about $0.0041 \mathrm{~kg} / \mathrm{m}^{3}$ (assuming $\mathrm{m}_{\mathrm{CO}_{2}}{ }^{\sim} 44 \mathrm{amu}$ ).

In conclusion, Mars requires an atmospheric $\mathrm{CO}_{2}$ density of over $0.0041 \mathrm{~kg} / \mathrm{m}^{3}$, as a bare minimum, in order to maintain an average surface air temperature capable of sustaining liquid water.

## 3 The Current State of Mars

### 3.1 The Martian Atmosphere

Mars has a current average atmospheric temperature of roughly 210 Kelvin ${ }^{[12]}$. This is due to the absence of a thick atmosphere which would otherwise trap the sun's energy. Mars' atmosphere has a density of roughly $0.02 \mathrm{~kg} / \mathrm{m}^{3}$ and a surface pressure of about $6.36 \mathrm{mb}^{[12]}$, which are roughly $1.7 \%$ and $0.6 \%$ of Earth's, respectively. The Martian atmosphere has a composition (by volume) of $95.32 \%$ Carbon Dioxide $\left(\mathrm{CO}_{2}\right), 2.7 \%$ Nitrogen ( $\mathrm{N}_{2}$ ), $1.6 \%$ Argon (Ar), $0.13 \%$ Oxygen $\left(\mathrm{O}_{2}\right)$ and traces of other compounds ${ }^{[12]}$. The mass of Mars' atmosphere is ${ }^{\sim} 2.5 \times 10^{16} \mathrm{~kg}$, based on a scale height of 11.1 km . Both the low temperature and atmospheric pressure prevent the existence of liquid water on

Mars' surface, excepting a limited amount during warmer seasons ${ }^{[1]}$. We calculate an approximation for the volume of Mars' atmosphere by treating it as a spherical section with a width equal to the scale height. The volume is then given by equation 5 and works out to be $1.59 \times 10^{18} \mathrm{~m}^{3}$.

$$
\begin{equation*}
V=\frac{4}{3} \pi\left(r_{\text {Mars }}^{3}-r_{\text {Mars }+ \text { ScaleHeight }}^{3}\right) \tag{5}
\end{equation*}
$$

### 3.2 Polar Ice Caps

Mars has two distinct polar caps which are comprised of a surface layer coating of solid carbon dioxide covering a significantly thick layer of water ice ${ }^{[9]}$. The exact size and shape of these caps has a dramatic seasonal dependence. It is known that during Martian Summers, at times the North pole completely vanishes due to sublimation, while the South pole never completely sublimates. In this paper we are interested only in this surface layer of solid carbon dioxide. The North pole of Mars features a layer approximately 1100 km in diameter and 1 m thick, while the South pole features a layer approximately 350 km in diameter and 8 m thick ${ }^{[9]}$. We compute a volume for the carbon dioxide stored in the North pole by modelling the North pole as a cylinder with a diameter of 1100 km and height of 1 m . Doing so, we arrive at a volume of $9.50 \mathrm{x} 10^{\wedge} 11 \mathrm{~m}^{\wedge} 3$. Similarly, the computed volume of carbon dioxide stored in the South pole is found to be $7.69 \times 10^{11} \mathrm{~m}^{3}$. Thus we find that at its coldest, Mars currently stores $1.72 \times 10^{12} \mathrm{~m}^{3}$ of carbon dioxide in its poles. By completely sublimating this stored $\mathrm{CO}_{2}$, we can thicken the atmosphere and initiate a greenhouse effect which can contribute to further warming the planet to desired levels.

### 3.3 The Heat Capacity of the Martian Atmosphere

In order to simplify future calculations, in particular that of optical depth and its effect on temperature, we approximate this atmosphere to be comprised of solely carbon dioxide. We take the specific heat capacity of the atmosphere to be equal to that of gaseous carbon dioxide, $735 \mathrm{~J} / \mathrm{kgK}$ at a temperature of $200 \mathrm{~K}^{[3]}$. Multiplying this capacity by the atmospheric mass given in section 3.1 gives an energy value of $1.8375 \times 10^{19} \mathrm{~J}$ needed to raise the entire atmosphere's temperature by one Kelvin.

## 4 Generation of the Greenhouse Effect

A large body colliding with Mars will increase the overall temperature of the planet as energy is added to the system. Not all of the energy of the colliding body will go towards heating the surroundings and eventually, by dissipation, the planet. Following from the results of a simulation done by Maindl et. al. (2015), we expect a weak dependence for energy transfer on size of colliding body and a strong dependence on angle of impact ${ }^{[7]}$. Adapting the methodology of Maindl et. al. (2015), we also relate the energy available as heat from the collision to be $60 \%$ of the kinetic energy of the colliding object ${ }^{[7]}$.

We decided to choose a series of collisions such that the energy available is sufficient to heat the planet enough to amplify the current greenhouse effect by adding all of the stored carbon dioxide from the poles to the atmosphere. This thickening enhances the ability of the atmosphere to absorb and retain heat, leading to higher surface temperatures and the ability to support liquid water.

### 4.1 Initial Atmospheric Heating

A series of ten impacts heat the atmosphere to a temperature sufficient to start sublimation. The coldest temperature recorded at the polar regions of Mars was 123 K , we require that this be raised to 150 K to allow for sublimation to occur ${ }^{[9]}$. The mechanism for generating this heat is the impacts themselves, so we require that the collisions provide enough energy to raise the temperature by 27 K . After this initial atmospheric heating, temperatures at the polar regions are high enough that even during the coldest seasonal period of Mars sublimation can occur.

### 4.2 Sublimation of the Polar Caps

From 3.2, we know that the total volume available for sublimation is $1.72 \times 10^{12} \mathrm{~m}^{3}$. Were the poles to completely sublimate, this would add a large amount of carbon dioxide to the atmosphere. We ignore the timescale over which this sublimation occurs as it is not of interest to us in this first approximation of creation of a suitable environment for liquid water to exist. Using a density of $1600 \mathrm{~kg} / \mathrm{m}^{3}$ [2], this corresponds to a mass of $2.75 \times 10^{15} \mathrm{~kg}$ of carbon dioxide being added to the atmosphere. Thus, the amount of carbon dioxide in the atmosphere after the asteroid impacts is $2.78 \times 10^{16} \mathrm{~kg}$. This will correspond to a new atmospheric density of $0.0175 \mathrm{~kg} / \mathrm{m}^{3}$.

### 4.3 The New Optical Depth

The new atmospheric number density of $\mathrm{CO}_{2}$ will be about $2.38 \times 10^{23} \mathrm{~m}^{-3}$. Using equation 4 , we find that the new optical depth of $\mathrm{CO}_{2}$ is about 54.45 . The corresponding surface air temperature appears to be between 285 K and 286 K , according to Figure 1. This is sufficient for liquid water to exist on the surface of Mars.

## 5 Required Energy

The energy required to change Mars to a state capable of supporting liquid water on its surface comes from the ten collisions. From 4.1 we require that the collisions provide enough energy to raise the temperature by 27 K , and from 4.2 we require that they also provide enough energy to completely sublimate the poles. The energy required to raise the temperature by 27 K follows from equation 6 , which gives a value of $4.961 \times 10^{20} \mathrm{~J}$.

$$
\begin{equation*}
\Delta E=\text { HeatCapacityOf Atmosphere } \times 27 K \tag{6}
\end{equation*}
$$

The energy required to sublimate the poles is given by equation 7 , where m is $1.72 \times 10^{12} \mathrm{~m}^{3}$ from 3.2 , M is the molar mass, $\sim 44 \mathrm{amu}$ and $\Delta \mathrm{H}$ is the enthalpy of sublimation, $26.3 \mathrm{~kJ} / \mathrm{mol}^{[2]}$. This energy works out to be equal to $1.64 \times 10^{21} \mathrm{~J}$.

$$
\begin{equation*}
\Delta E=\frac{m_{\text {IceCap }}}{m_{C O_{2}}} \Delta H \tag{7}
\end{equation*}
$$

From the two energies above, we conclude that the impacts must provide a total energy of $2.14 \times 10^{21} \mathrm{~J}$ to change the state of Mars. Providing that the energy transfer from the collisions has an efficiency of $60 \%$, as discussed in section 4 , an estimate for total mass of colliding objects can be obtained from equation 8 .

$$
\begin{equation*}
\sum m_{i}=\frac{2 \Delta E}{0.6 v^{2}} \tag{8}
\end{equation*}
$$

Following the equation above and assuming a collision velocity of $\sim 24 \mathrm{~km} / \mathrm{s}$, we find that the total mass required is $1.225 \times 10^{13} \mathrm{~kg}$. This required collision velocity was chosen arbitrarily, but led to a very physical size estimate for the colliding bodies, and so was kept.

## 6 Asteroid Hunting

From section 5 , it is apparent that we must find 10 bodies whose total mass adds to $1.225 \times 10^{13} \mathrm{~kg}$ to collide into Mars. We decide that such candidates are best found in the population of Mars-crossing asteroids and the asteroid belt itself. Prior to searching for specific candidates, we decide to specify an ideal asteroid to which we may compare candidates.

This ideal asteroid is spherical in shape, is solid and of uniform density, a circular orbit on the plane of Mars, and contains one tenth the required total mass $\left(1.225 \times 10^{12} \mathrm{~kg}\right)$. The asteroid must be able to withstand the strains of approaching Mars and travelling through its atmosphere. Upon impacting Mars, this ideal asteroid will transfer most of its kinetic energy into heat, and will have lost no energy in the process of travelling through Mars' atmosphere.

Certainly no real asteroids are expected match the all the criteria. In fact, none are expected to match any of the criteria; however, they serve to set a good baseline. From the NASA data sheet on the asteroid belt, we see that the best candidates (mass-wise) will be asteroids similar to Icarus ${ }^{[11]}$. Since it is difficult to calculate the mass of an asteroid, it is rarely done and thus any database of asteroids, such as the one used to find candidates, lacks this information. As a result we have to make the assumption that if we choose bodies similar in diameter to Icarus, their masses will be of similar scale. We set a range of diameters of $1.0 \mathrm{~km}-2.0 \mathrm{~km}$ as a search criterion and end up choosing the ten bodies listed in table 1, obtained from the Jet Propulsion Laboratory database ${ }^{[6]}$.

## 7 Asteroid Energies and Impulses

### 7.1 Virial Theorem

Using the Virial Theorem, we can determine the change in orbital energy of an asteroid when we move it from its initial orbit to a similar, stable, Martian orbit. The orbital energy of an object in the solar system is given by the equation below, where $\mathrm{M}_{\text {Sun }}$ is the solar mass, a is the semi-major axis of orbit, and $\mu$ is the mass of the orbiting body.

$$
\begin{equation*}
E_{\text {Total }}=\frac{-G M_{\text {Sun }} \mu}{2 a}=-E_{\text {Kinetic }}=\frac{E_{\text {Potential }}}{2} \tag{9}
\end{equation*}
$$

Thus, the change in orbital energy can be described below. An extra term has been added to account for the extra relative velocity between the asteroid and Mars that we wish for the bodies to collide with $(24 \mathrm{~km} / \mathrm{s}$ as was chosen earlier).

$$
\begin{equation*}
\Delta E=\frac{-G M_{\text {Sun }} \mu}{2}\left(\frac{1}{a_{\text {Mars }}}-\frac{1}{a_{\text {Asteroid }}}\right)+\frac{1}{2} \mu v_{r e l}^{2} \tag{10}
\end{equation*}
$$

### 7.2 Impulse

The impulse, J , required for this action is described below using changes in total momentum, rather than momentum as a vector. The downside to using this method is that we don't know which direction we are pushing the asteroid, only how hard. Another method that involves slowing down the tangential velocity of the asteroid will be discussed in the next section, but it is incomplete. In our equation, $\mathrm{a}_{\mathrm{Mars}}$ is the semi-major axis of Martian orbit, and $\mathrm{a}_{\mathrm{Asteroid}}$ is the semi-major axis of the asteroid's initial orbit. Again, $v_{\text {rel }}$ was chosen to be $24 \mathrm{~km} / \mathrm{s}$.

$$
\begin{equation*}
J=\Delta p=\mu\left(\left(v_{f}+v_{r e l}\right)-v_{i}\right)=\mu\left(\sqrt{\frac{G M_{\text {Sun }}}{a_{\text {Mars }}}}-\sqrt{\frac{G M_{\text {Sun }}}{a_{\text {Asteroid }}}}+v_{r e l}\right) \tag{11}
\end{equation*}
$$

### 7.3 Sending an Imaginary Asteroid to Mars

As an example, we will determine the energy and total impulse required to send an ideal asteroid (described in section 6) on a collision course towards Mars. The mass of our asteroid is $1.225 \times 10^{12} \mathrm{~kg}$. Assuming its initial orbit lies within the asteroid belt ( $\mathrm{a}^{\sim} 3 \mathrm{AU}=4.5 \times 10^{11} \mathrm{~m}$ ). Using equation 10 , we determine that the energy required to send our rock to Mars is $1.77 \times 10^{20} \mathrm{~J}$. This is equivalent to about 42000 megatons of TNT. As a comparison, the Tsar Bomba was the largest nuclear detonation on Earth. It was recorded to release an energy of about 50 megatons. We would need a significantly larger amount of energy to move even one asteroid in such a way that we could hit Mars hard enough to terraform it.

Using equation 11, we can also determine that the total impulse needed to move our imaginary asteroid would be about $3.79 \times 10^{16} \mathrm{~kg}^{*} \mathrm{~m} / \mathrm{s}$.

### 7.4 Sending Real Asteroids to Mars

By applying the same steps in 7.3 , we can determine the energies and impulses required to smash the asteroid candidates from section 6 into Mars. The mass of each asteroid is estimated to be of the same order as Icarus. This data is shown in the table below.

| Asteroid | Semi-major Axis ${ }^{[10]}$ [m] | Eccentricity | Diameter [km] | Mass [kg] | $\Delta \mathrm{E}[\mathrm{J}]$ | J [kg*m/s] |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| Icarus ${ }^{[11]}$ | $1.61267 \mathrm{e}+11$ | 0.82690 | 1.4 | 1 e 12 | 4.08 e 20 | 1.94 e 16 |

Table 1: Asteroid Candidates to Terraform Mars

## 8 Discussion

### 8.1 Timing of Impacts

Our model assumes that the impact energy in the form of heat (and therefore the change in temperature) is communicated instantly. In reality there is some timescale over which this operates, one that depends on the density of the atmosphere, the difference between the temperature of the impact region and the rest of the atmosphere, and the contents of the atmosphere. If this timescale is comparable to or greater than the timescale of total heat dissipation through the atmosphere, then an impact at an arbitrary location will have a significant-or even total- reduction in efficiency. Depending upon the severity of this reduction it may be enough to simply reduce the delay between impacts. Otherwise, directing the initial impacts toward the poles in order to reduce dissipation might cause the release of enough $\mathrm{CO}_{2}$ to reduce the dissipation associated with future collisions.

### 8.2 Molecules Escaping the Atmosphere

In heating up the Martian atmosphere, we need to be careful that we aren't increasing the surface air temperature over the point at which $\mathrm{CO}_{2}$ molecules begin to gain enough speed to escape Mars' gravitational potential and escape the atmosphere. The rate of particles leaving the atmosphere is given by the following equation ${ }^{[4]}$. R is the radius of the outer edge of the atmosphere. n is the number density of the atmosphere (determined to be $2.83 \times 10^{23} \mathrm{~m}^{-3}$ earlier).

$$
\begin{equation*}
\dot{N}=4 \pi R^{2} v n \tag{12}
\end{equation*}
$$

$\nu$ is characterized by the following equation ${ }^{[4]}$, where m is the mass of each particle ( 44 amu ), k is the Boltzmann constant, and T is the temperature (we determined earlier that the new equilibrium surface air temperature would be about 286 K ).

$$
\begin{equation*}
v \equiv \frac{1}{8} \sqrt{\frac{m}{2 \pi k T}}\left(v_{e s c}^{2}+\frac{2 k T}{m}\right) e^{-m v_{e s c}^{2} / 2 k T} \tag{13}
\end{equation*}
$$

$\mathrm{v}_{\mathrm{esc}}$ is the escape velocity described by the equation below. M is the mass of Mars (about $6.42 \times 10^{23} \mathrm{~kg}^{[12]}$ ).

$$
\begin{equation*}
v_{e s c}^{2}=\frac{2 G M}{R} \tag{14}
\end{equation*}
$$

These equations result in a calculated $N$ of about $4.57 \times 10^{-61} \mathrm{~s}^{-1} . \mathrm{N}^{\sim} \mathrm{nV}=4.5 \times 10^{41}$, where the volume of the atmosphere was determined earlier to be $1.59 \times 10^{18} \mathrm{~m}^{3}$. We determine that the time for all the $\mathrm{CO}_{2}$ to leave the atmosphere is $t_{\text {esc }}=N / \dot{N}=9.85 \times 10^{101} s=3.12 \times 10^{94}$ years. We won't need to worry about $\mathrm{CO}_{2}$ escaping from the Martian atmosphere any time soon.

### 8.3 Using Angular Momentum to find the Impulse of Asteroids

We can send asteroids towards Mars by slowing down their motions in the tangential direction of their orbits. This would result in the asteroid spiralling inwards. Assuming the impulses to the asteroids are instantaneous, we would have a tangential velocity $\mathrm{v}_{\vartheta}$ of the asteroid that remains the same after we push it. This can be determined with our impulse. The final angular momentum can be represented in the following way, assuming that the final stabilized orbit of the asteroid is circular, with a radius $r\left(\mathrm{v}_{\mathrm{r}}=0\right)$.

$$
\begin{equation*}
L^{2}=G M r \mu^{2}=\frac{\mu^{2} v_{\theta}^{2}}{r^{2}} \tag{15}
\end{equation*}
$$

Since the tangential velocity should remain constant after we push it, we can represent it as follows.

$$
\begin{equation*}
v_{\theta}^{2}=G M r^{3} \tag{16}
\end{equation*}
$$

In order for the asteroid to spiral into a smaller orbit, its radial velocity would need to change. We want it to change in such a way such that the asteroids relative velocity with Mars is about $24 \mathrm{~km} / \mathrm{s}$ as it passes through Martian orbit.

$$
\begin{equation*}
v_{r e l}=v_{M a r s}-\sqrt{v_{r}^{2}+v_{\theta}^{2}}=-24 \mathrm{~km} / \mathrm{s} \tag{17}
\end{equation*}
$$

Since $\mathrm{v}_{\text {Mars }}$ is also about $24 \mathrm{~km} / \mathrm{s}$, we want $v_{r}^{2}+v_{\theta}^{2}=v_{r}^{2}+G M r^{3}=(48 \mathrm{~km} / \mathrm{s})^{2}$. This gives us a relation between $\mathrm{v}_{\mathrm{r}}$ and r , the final stable radius of the asteroid's orbit assuming it doesn't collide with Mars. Finding a final orbital radius that allows the asteroid to travel through the Martian orbit such that equation 17 is satisfied would allow us to find the impulse that we need to push the asteroid with. The direction of impulse would simply be in the opposite of its initial tangential motion. We do not know how to model an orbit spiralling inwards, so this method was too difficult for us to use, but it could be used to find a more efficient method of sending the asteroids to Mars.

## 9 Conclusion

Our analysis suggests that the total energy necessary to sublimate the amount of carbon dioxide needed to create atmospheric conditions conducive to the existence of liquid water is roughly $2.14 \times 10^{21} \mathrm{~J}$, accounting for both the energy necessary to heat the atmosphere and the energy needed to fuel the state transition. Based on our assumption about the impact velocity, this corresponds to a total required mass of $1.225 \times 10^{13} \mathrm{~kg}$. Assuming that this mass is distributed evenly between all of the asteroids, and that these asteroids are located in the asteroid belt, the impulse required to place them on a collision course with Mars is on the order of $10^{16} \mathrm{~N}$ * .

## Appendix - Code

The following code was used to produce Figure 1.

```
## Team 190 - opticaldepth.py
## This code was used to calculate the optical depth of CO2 and plot a graph
## of the optical depth required for liquid water to exist on Mars.
import numpy as np
from matplotlib import pyplot as plt
# Optical depth as a function of surface air temp and blackbody temp
def optical(T_surf, T_bb):
```

```
                                    (float(T_bb)**4. - (0.3)*float(徆_surf)**4.))
# Range of temperatures allowing for liquid water
ts = np.arange(273, 290)
# Blackbody temp of Mars is about 215K
tbb = 215.
opt = []
for i in ts:
            opt.append(optical(i, tbb))
opt = np.array(opt)
print opt[0], opt[-1]
plt.plot(ts, opt, label='Optical depth of CO2')
plt.xlabel('Surface Air Temperature [K]')
plt.ylabel('Optical Depth')
plt.legend (loc=2)
plt.title('Optical depth of CO2 required for surface air temperatures on Mars')
plt.show()
```
